Management Summary

Prediction of the stock market using historical trend is noticeably challenging, and it has been the area of research for many decades. The report analyzes technical aspects of stock price movements based on a machine learning model, particularly using Logistic Regression (LR) and Naive Bayes (NB) algorithms. The study will examine the effectiveness of model prediction in stock price movement in trading strategies considering with and without trading cost.

Technical analysis opposes the fundamental theory of the Efficient Market Hypothesis (EMH) as well as Random walk Hypothesis as market direction cannot be estimated through historical data analysis. However, in recent years some statistical model integrated in machine learning algorithm has some ability to anticipate the movement of stock prices (Dongdong Lv et. al 2019).

Logistic regression is a classification model to classify the binary or multi-class label based on multiple independent variables. It uses the sigmoid activation function (appendix 1) to calculate each class's probability, where a predefined threshold determines the class label. It can be applied to predict the stock market movement (e.g., up or down) using single or numerous features as independent variables. The naive Bayes is another type of classification model based on the Bayes theorem that assumes features independence on each other and estimates features prior probability and likelihood probability with each attribute for each class to calculate the posterior probability using the Bayes formula. The higher probability predicts the class label.

Different indices, stocks, and commodities/currencies have been extracted from yahoo finance and onvista into python, and the closing price is taken as the base price. Logarithmic return of assets closing price assures the data stationarity. Jarque-Bera test validates the dataset's log return is normally distributed (see appendix 2). The binary value of log return eliminates the seasonality and trend from the datasets. Class label as Upward [1] and Downward [-1] movement has been obtained from log return where the threshold is 0. Different binary lag variables, e.g., five lags, five digitized lags, five ROC lags, have been created to perform the test within the model. From Appendix 3, Table:1, it has been observed that digitize lag features

produce higher cumulative returns while conducting vectorized backtesting with relatively similar volatility. Therefore, findings of digitized lag feature employed in different trading strategies.

Performance evaluations have been conducted with two different portfolios to \$100,000 and \$10,000, respectively, while considering the trading cost. From Appendix 4, Table:3 shows that eleven assets beat traditional buy and hold strategy return while considering no trading cost. With considering the trading cost, yields are sensitive to different portfolios. For Example, Dow Jones produces a 276% cumulative return in the higher portfolio amount in the Logistic Regression model, whereas only 18% in the lower portfolio cannot beat the benchmark return of 87%. This trend holds almost for all the asset categories. Therefore it shows lower portfolio amount yields relatively very low compare to the higher portfolio amount.

Another type of performance evaluation has been considered with the python library "Backtrader" that helps traders develop their trading strategies and evaluate the performance using python library "pyfolio" developed by quantipion. The Initial Portfolio amount is \$100,000 with a 0.09% commission on each transaction without considering short selling. The strategy is, when the next day prediction according to the models is higher than 0, it will buy the shares with the next day opening price as much as possible within portfolio amount and sell owned shares when the prediction is negative. Appendix 5 demonstrates that the trading strategy using backtrader beat the usual strategy with higher return without considering the trading cost. However, returns are relatively low, even negative in some cases, including the trading cost. Appendix 5 Table 4.3 indicates that Ahold's performance is very satisfactory without any trading cost, but with trading cost, no transaction occurs during the backtesting period.

In a nutshell, from the above studies, it can be perceived that technical analysis beat the conventional approach among all asset classes without considering the trading cost. However, it produces inadequate yields while commission added in transactions, even worst in a lower portfolio amount. In most cases, both model's accuracy exceeds 51%, slightly better than random guessing.

Appendix 1:

Equation of Logistics Regression and Naïve Bayes

Sigmoid Activation Function:

$$g(z) = \frac{1}{1+e^{-z}}$$

Where,

$g(z)$ = Output between 0 and 1 (Probability Estimate)

z = input to the function

e = base of natural log

Naïve Bayes:

$$y = \operatorname{argmax}_y P(y) \prod_{i=1}^n P(x_i|y_i)$$

Where,

$P(y)$ = Class Probabilit

$P(x_i|y_i)$ = Conditional Probability
